RESULTS

Variation in the number of factors retained

To compare the 55 factors generated from a single to 10-factor solution (Figure 3A), we reran regression models per task, including each factor within independent models, along with age, gender and education/IQ. Replicating the findings when factor scores from each solution were included in the same model (Figure 3A), no factor outperformed the benchmark of 'Compulsivity and Intrusive Thought' for the association with model-based planning (Figure S1). For associations with metacognitive bias, we found that no factor outperformed the benchmark of 'Compulsivity and Intrusive Thought' in terms of a positive association with metacognitive bias (i.e., higher confidence) (Figure S1), again replicating the top performance of 'Compulsivity and Intrusive Thought' when factors from the same solution were included in the same model (Figure 3A). The first factor from a 4-factor solution had a stronger negative association with metacognitive bias than 'Anxious-Depression' (Figure S1), which contrasted the top effect of the first factor in a 2-factor model when all solution factors were included in the regression model (Figure 3A). Notably, including the factors from each solution in separate regression models produces top effects that are relatively smaller in magnitude than the effects from models that include all factors within a solution, especially for metacognitive bias (magnitude of effects in Figure 3A vs Figure S1). For example, the magnitude of the effect of 'Compulsivity and Intrusive Thought' on confidence bias is nominally larger when factors from the same solution are included in the model (Cohen's $f^2 = 0.037$, Figure 3B) compared to when the other factors are not controlled for (Cohen's $f^2 = 0.025$, Figure S1). This is also the case for Anxious-depression: Cohen's $f^2 = -0.030$ when other 2 factors from the solution are included in the model (Figure 3A), Cohen's $f^2 = -0.022$ when factors are in separate models (Figure S1). This demonstrates the importance of including factors from the same solution in a single regression model, to control for factors with opposing effects on metacognitive bias (e.g., 'Anxious-Depression' vs. 'Compulsivity and Intrusive Thought').

Scores on the 2nd factor from this same 2-factor solution were also highly correlated with 'Compulsivity and Intrusive Thought', $r(207) = .93$, $p < 0.001$ (Figure S2A), and loadings were correlated at $r(207) = 0.84$, $p < 0.001$, with the main difference in loadings also being attributed to social-anxiety items (Figure S2B), which in a 3-factor solution forms its own factor termed 'Social Withdrawal' in prior work (Gillan et al., 2016).

Figure S1. Re-analyses of variation in the number of factors retained, without controlling for other factors from that model. Fifty-five factors were generated from solutions retaining 1-factor, 2-factors, ..., 10-factors. Heatmap indicates the loading of individual items onto each resulting factor (top panel). Weighted effect sizes from 10 linear regression analysis predicting model-based planning, averaged across 5 datasets (N=4990) (middle panel) and metacognition in 4 datasets (N=2575) (bottom panel), when factors are included in separate regression models.

Figure S2. Re-analyses of variation in the number of factors retained, without controlling for other factors from that model. CIT=Compulsivity and Intrusive Thought. **(A)** Correlation between scores on the 2nd factor in a 3-factor solution (model 3.2 i.e., 'Compulsivity and Intrusive Thought') and the 2nd factor from two factor solution (model 2.2) in the discovery dataset. **(B)** Correlation between factor loadings of Compulsivity and Intrusive Thought and model 2.2 in the discovery dataset.

Variation in the selection of clinical symptoms

For the association with deficits in model-based planning, the top performing factor and 'Compulsivity and intrusive thought' both had highest loadings for OCD items and the lowest loadings for apathy items, with the top factor being generated from a set of questionnaires that omitted the schizotypy and alcohol addiction scales (Figure S3A). Examining loadings for the top performing factor that predicted overconfidence omitted the trait anxiety and eating disorder questionnaires were omitted (Figure S3B). While the top performing factor for associations with underconfidence also omitted the eating disorder questionnaire, this factor had the highest loadings for the trait anxiety items (Figure S3C).

Visualising the item-level loadings across the top 1500 dimensions associated with deficits in model-based planning, items related to obsessive-compulsive disorder appears to have relatively stronger positive loadings across dimensions (Figure S4A). This was confirmed when averaging item-level loadings across the top 100 dimensions (Figure S5A). Items related to obsessive compulsive disorder ($M=0.51$, $SD=0.01$), followed by eating disorders ($M=0.20$, $SD=0.07$), had the highest average questionnaire-level loadings, while apathy items had the lowest average loading ($M=-0.01$, $SD=0.03$) across the top 100 dimensions associated with deficits in model-based planning (Figure S5D). For associations with overconfidence, a heatmap of the top 1500 dimensions illustrated the relative importance of items related to obsessive-compulsive disorder, impulsivity and schizotypy (Figure S4B). Similar to the top dimensions associated with deficits in model-based planning, items from the obsessive compulsive disorder questionnaire contributed most predominantly to the top 100 dimensions (Figure S5B) and had the highest questionnaire-level average loadings ($M=0.36$, $SD=0.02$) (Figure S5D). Additionally, items related to impulsivity ($M=0.22$, $SD=0.04$) and schizotypy ($M=0.20$, $SD = 0.03$) had relatively higher average loadings on the top 100 dimensions that explained individual differences in overconfidence (Figure S5B-D).

When examining negative associations with confidence bias, trait anxiety items had strong positive loadings across the top 1500 performing dimensions (Figure S4C). The relative importance of trait anxiety items was confirmed by averaging loadings across the top 100 dimensions, at the item-level (Figure S5C) and questionnaire-level ($M=0.59$, $SD=0.02$) (Figure S5D). In contrast to trait anxiety, the depression questionnaire was completely omitted from the top 100 dimensions (Figures S4C & S5C), indicating that removal of the depression questionnaire generates dimensions sensitive to individual differences in underconfidence. The relative importance of trait anxiety was specific to underconfidence, as trait anxiety had lower loadings across the top 100 dimensions predicting model-based planning ($M=0.06$, $SD=0.05$) and overconfidence ($M=0.06$, $SD=0.05$). While obsessive compulsive disorder items had the highest loadings across the top 100 dimensions for overconfidence ($M=0.36$, $SD=0.02$) (Figures S5B and S5D), obsessive compulsive disorder items did not load relatively highly across dimensions for underconfidence ($M=0.02$, $SD=0.03$) (Figures S5C-D). This suggested that over- and under-confidence have differential associations with psychopathology (i.e., overconfidence with OCD vs. underconfidence with trait anxiety), rather than merely representing effects with opposing directionality on the same clinical phenomena.

Figure S3. Top (1/7665) performing dimensions from varying the selection of clinical symptoms. OCD = obsessive compulsive disorder. The left side of the panel includes loadings for the 209 questionnaire items across the top performing factors with largest effect sizes for the associations with **(A)** model-based planning, **(B)** overconfidence, and **(C)** underconfidence (left-side of panel). On the right-side are loadings for the 209 items on the benchmark dimensions ('Compulsivity and Intrusive Thought' and 'Anxious-depression').

Figure S4. Heatmaps of top 1500/7665 performing dimensions from varying the selection of clinical symptoms. CIT=Compulsivity and Intrusive Thought. A-D=Anxious-depression, OCD= Obsessive compulsive disorder. Heatmaps for top 1500 dimensions with largest weighted average effect sizes for associations with **(A)** model-based planning, **(B)** overconfidence (positive mean confidence), and **(C)** underconfidence (negative mean confidence).

Figure S5. Average across top 100/7665 performing dimensions from varying the selection of clinical symptoms. OCD = Obsessive compulsive disorder. Average loadings for the 209 questionnaire items across the top 100 dimensions with largest effect sizes for the associations with **(A)** model-based planning, **(B)** overconfidence, and **(C)** underconfidence. **(D)** The average questionnaire-level loadings across the top 100 dimensions associated with cognitive outcomes. Questionnaire colours in (D) correspond to item colours in (A-C) (e.g., grey = apathy item/questionnaire-level loadings).

Higher- versus first-order factor rotation

The within-solution correlations between factor scores verified the oblique and orthogonal nature across rotation types. The oblique rotation 'oblimin' produces correlations between factors 1,2 and 3 ranging from 0.28-0.43, compared to the orthogonal rotation 'varimax', which ranged from $r=-.06$ to $.08$ (Figure S6). Applying a bifactor rotation produced factor structures that were internally orthogonal, with correlations between factors 1,2, 3 and the hierarchical general 'G' factor all at $r=0$ (Figure S6).

Figure S6. Higher- versus first-order factor rotation: The within-solution correlations between factor scores. F1= factor 1, F2 = factor 2, F3 = factor 3, 'p' = general factor. The within-solution correlations indicated strong positive correlations within the oblimin (oblique) solution, and very weak/no correlation between factors within the orthogonal solutions 'varimax' and the bifactor model.

Figure S7. Higher- versus first-order factor rotation. AMT = Amazon's Mechanical Turk. p = general factor extracted from bifactor model. (A) Correlation of scores on factor 1, 2 and 3 from the 3 derivations – oblique, orthogonal and bifactor models in the discovery dataset (N=1413). Each correlation matrix also includes the correlation to the bifactor models general ('p') factor. (B) Weighted effect size for the association between derived factors and model-based planning and metacognitive bias. An oblique solution produces the winning model in all cases. (C) Individual results from component datasets for the 'p' factor reveals no consistent pattern of association with the cognitive constructs in question.

Partial Least Squares Regression

Figure S8. Weights of items across components generated with Partial Least Squares Regression. OCD = Obsessive compulsive disorder. The 209 questionnaire item weights for the components generated with partial least squares regression to predict individual differences in **(A)** model-based planning, **(B)** overconfidence, and **(C)** underconfidence.

Table S1. Individual questionnaire items and weights for the Partial Least Squares Regression solutions, Anxious-depression and Compulsivity and Intrusive Thought.

AES = Apathy (Apathy Evaluation Scale), AUD = Alcohol misuse (Alcohol Use Disorders Identification Test), BIS = Impulsivity (Barratt Impulsiveness Scale 11), EAT = Eating (Eating Attitudes Test), LSA = Social anxiety (Liebowitz Social Anxiety Scale), OCI = OCD (Obsessive-Compulsive Inventory-Revised, OCI-R), SCZ = Schizotypy (Short Scales for Measuring Schizotypy), SDS = Depression (Zung Self-Rating Depression Scale), STA = Trait anxiety (State Trait Anxiety Inventory), pls_mbi = weights for the PLS factor predicting model-based planning (negative association), pls_overconf = weights for the PLS factor predicting (over)confidence (positive association), pls_underconf = weights for the PLS factor predicting (under)confidence (negative association), AD = Anxious-depression, CIT = Compulsivity and Intrusive Thought.
